Programming language design and analysis

Types

Marius Minea

9 October 2017
Types: what and why?

A simple definition (first programming course):
“Type = set of values together with some operations on that set”

A trivial error (at the ML prompt):
# (+) 3 (fun x -> x);;
Error: This expression should not be a function,
the expected type is int

⇒ Some (syntactically correct) programs do not make sense
Types: a filter for bad programs

Generalizing:
“A type is any property of a program that we can establish without executing the program” Krishnamurthi, PLAI book

**Type system**
a mechanism for distinguishing good programs from bad
(informally)

“A type system is a tractable syntactic method for proving the absence of certain program behaviors by classifying phrases according to the kinds of values they compute” Pierce
Can we always type things?

(+ 1 (if unknown then 3 else (fun x -> x)))
   would run OK if unknown is true
   would give an error otherwise
⇒ can’t (always) decide

Type systems are always prey to the Halting Problem.
⇒ a type system for a general-purpose language must always
either over- or under-approximate:
   either must accept programs that will error when executed
or must reject programs that might have run without error

Krishnamurthi, PLAI
Types as a means to organize

[Cardelli and Wegner, 
On Understanding Types, Data Abstraction and Polymorphism]

The following are \textit{untyped} universes

bit-strings in computer memory
  everything represented as bit-strings $\Rightarrow$ untyped/only one type

S-expressions in (pure) Lisp
  no distinction between program and data
  but: some structure (more than bit-strings)

$\lambda$-expressions in the $\lambda$-calculus
  everything is a function (numbers, booleans, if-then-else)

Sets in set theory
  everything is an element or a set (can encode mathematics...)
Even simple things can be classified

Bitstrings can represent operations or characters, integers, ...

Some S-expressions are lists, others are LISP programs

Some $\lambda$– expressions (functions) represent booleans, or integers

Some sets may denote ordered pairs, leading to functions
  $\Rightarrow$ Can think of untyped universes as typed
  But this is an illusion unless there is some means to enforce it

Typing may be:
  explicit (types part of syntax, e.g. all variables typed)
  implicit (can be reconstructed: type inference)
Types as protective mechanism

Types avoid problems related to exposing internal representation
Types impose constraints which help to enforce correctness
Types avoid logical inconsistencies ("set of all sets")
Types prevent inconsistent interactions between objects

“A type may be viewed as a set of clothes (or a suit of armor) that protects an underlying untyped representation from arbitrary or unintended use.” Cardelli & Wegner

“Violating the type system involves removing the protective set of clothing and operating directly on the naked representation.”
A program might have:  

*trapped errors*: cause computation to stop  
*untrapped errors*: may go unnoticed

A program (fragment) is *safe* if it does not cause untrapped errors.

A *safe* language: all program fragments are safe.

But, we want more...  
no untrapped errors  
no trapped errors that we consider *forbidden errors*  
programmer must avoid other trapped errors
Static and Strong Typing

**Static Typing**

type of every expression can be determined by static analysis at compile-time, e.g., ML, Java, Pascal (partly unsafe)
well-typed programs are well-behaved (conservatively)

**Strong Typing**

Languages in which all expressions are type-consistent
although type itself may be statically unknown
can be done by introducing some run-time type checking

Static implies strong typing, but strong typing could be dynamic

**Weak Typing** (weak checking)
some unsafe operations detected
Pascal: untagged variants and function parameters unsafe
Modula-3: separates safe/unsafe modules
Kinds of Polymorphism

Strachey (1967) defines:
– *parametric polymorphism*: function works uniformly on a range of types (with some common structure)
– *ad-hoc polymorphism*: function works on several different types (may not have common structure), may behave in unrelated ways

Refined classification [Cardelli and Wegner]:

Polymorphism

\[
\begin{align*}
\text{universal} & \quad \{ \text{parametric inclusion} \} \\
\text{ad-hoc} & \quad \{ \text{overloading coercion} \}
\end{align*}
\]
Universal polymorphism

**Parametric polymorphism**
Use of a single abstraction across different types
e.g. list abstraction ‘a list

**Inclusion polymorphism**
subtyping and inheritance
Ad-hoc polymorphism

Overloading
different functions with same name; context used to make decision
could view as syntactic abbreviation handled by preprocessing
e.g. multiple methods with same name, if signatures are distinct

Coercion
semantic operation, converts a type to that expected by a function
(otherwise type error would occur)
can be done statically or dynamically

Distinction blurred at times. Discuss:
3 + 4     3.0 + 4     3 + 4.0     3.0 + 4.0
Monomorphism and exceptions [Cardelli & Wegner]

**Overloading**: integer constants may have both type int and real. purely syntactic

**Coercion**: an integer value can be used where a real is expected conversions inferred at compile time (or even runtime: LISP)

**Subtyping**: elements of subrange type also belong to supertype.

**Value sharing**: nil constant shared by all the pointer types (Pascal) example of parametric polymorphism
4 kinds of polymorphism, revisited

- Coercion:
  a single abstraction serves several types through implicit type conversion

- Overloading:
  a single identifier denotes several abstractions

- Parametric:
  an abstraction operates uniformly across different types

- Inclusion:
  an abstraction operates through an inclusion relation

[Wm. Paul Rogers, Reveal the magic behind subtype polymorphism, JavaWorld, 2001]
Duck Polymorphism

"when I see a bird that walks like a duck and swims like a duck and quacks like a duck, I call that bird a duck."

a form of dynamic typing
  concerned with just the aspects of an object that are used, rather than the type of the object itself (entire interface).

Offers more freedom (polymorphism without inheritance)
Does not define an explicit interface
Can result in semantic unintended behavior
Simple type inference

Consider a lambda-calculus with integer constants.

Expressions are defined recursively as:

\[ E ::= n \mid x \mid \lambda x. E \mid E \; E \]

Types are defined recursively as:

\[ T ::= \text{int} \mid \alpha \mid T \to T \]

where \( \alpha \) is a *type variable* (still unbound type)

Type rules impose constraints (matching) on types, e.g.

\[ t(e_1 \; e_2) = \tau \quad \Rightarrow \quad t(e_1) = t(e_2) \to \tau \]
Union-Find

Datastructure + algorithm for working with equivalence classes

Operations:
- \textit{find}(element): finds representative of equivalence class
- \textit{union}(elem1, elem2): declares elements to be equivalent

Implementation: forest of \textit{trees} with links up to parent
- \textit{find}: returns tree root (node itself, it standalone)
- \textit{union}: links root of one tree to the other
Union-Find example

\[ \text{find}(X) = \text{find}(Y) = \text{find}(Z) = Z \]

\[ \text{union}(Y, S) \] links \( \text{find}(Y) \) and \( \text{find}(S) \)
Type inference: implementation hints

Unification leads to substitution
a type variable $\alpha$ can be substituted with any type term that does not contain $\alpha$ (no recursive types)
in $e_1 \ 4$, if $t(e_1) = \alpha$, then $\alpha = \text{int} \rightarrow \beta$ ($\beta$ = new type var)
Keep a mapping $\text{subst}$ from type variables to type terms

To unify two types, $t_1$ and $t_2$:
let $r_1 = \text{subst}^*(t_1)$ and $r_2 = \text{subst}^*(t_2)$
(recursively apply $\text{subst}$ to any variables in substitutions)
unify $r_1$ and $r_2$ (may change the $\text{subst}$ mapping)
a type variable can be unified with any type term that does not contain it (including another type variable)
a type constructor can be unified with the same constructor, by pairwise unifying arguments
$\rightarrow$ is a binary constructor, $\text{int}$ is 0-ary (type constant)
else fail, e.g., unify $\rightarrow$ with $\text{int}$
